Abstract

Title: Simulating improvements on mining compressed air systems
Author: B.M. Friedenstein
Supervisor: Dr Johann van Rensburg
School: North-West University Potchefstroom Campus
Degree: Masters in Electrical and Electronic Engineering

As operational costs of deep level mines increases and gold ore grades decrease, profitability in the gold mining sector is becoming a challenge. Electricity tariff increases have contributed to a rise in the cost of operating mines. Compressed air systems are utilised on mines as they provide safe, reliable power for various underground machines. Compressed air is also used for emergency oxygen in refuge bays.

Compressed air systems utilise a significant portion of a mine's total energy. It has been shown that many deep level mine compressed air networks have inefficiencies. Improving the efficiency of these systems could result in a reduction of operational costs by reducing the energy required to produce compressed air. Additionally, an improvement in service delivery could be achieved.

Previous studies have shown the usefulness of simulations to develop improvements for deep level mining systems. However, these studies have not followed a structured methodology for developing compressed air simulation for deep level mines. Previous studies have also simplified compressed air models reducing the simulation precision and testable scenarios.

In this study a simulation methodology was therefore developed. Investigations into the compressed air systems are performed. A model is then developed in software to accurately recreate the system operation. Finally a proposed means of improvement is simulated, analysed and quantified in terms of improvements in energy savings and service delivery.

Two case studies were evaluated. For each case study a variety of scenarios were simulated. In case study A by reducing air used by refuge bays in simulation, a reduction of 1 MW E.E. would be achieved with addition to a significant improvement of 18 kPa to system pressure. Drop tests implemented on the case studies validated the simulation with a precision of 5%.

The study showed that simulation is a important tool for identification improvements in large compressed air systems. By utilising a structured methodology to develop detailed compressed air simulations, inefficiencies and operational improvements were identified.

CHAPTER 1

Introduction and background

‘Quote.’ - Somebody

1.1 Preamble

This chapter firstly discusses background regarding deep level mining in South Africa. Next, the need to reduce costs of operation in the mining sector is examined. From this a focus in reducing energy consumption of compressed air systems is developed. Next, background on compressed air operation and energy interventions are discussed. Simulations and their value in industry is discussed leading to a problem statement and objectives of the study. Finally, an overview for the dissertation is provided.

1.2 Background on deep level mining

1.2.1 Mining profitability

Various technical, economic, social and operational challenges are posing a risk to the profitability of the South African mining sector. One of the challenges the sector faces is a rise in the cost of operation [1].

A considerable factor that is contributing to the rise of operational costs in South African gold mines has been the increase in electricity costs. As shown in figure 1.1, the general cost of electricity has increased at a rate greater than inflation since 2008 [2].

In addition to rising electricity costs, gold ore grades of South African mines have fallen substantially over the last few decades [3]. As ore grades decline, the energy utilised per unit of metal increases exponentially [4]. Therefore mines require significantly more energy per unit of metal produced. This combination of tariff increases and increased energy usage per unit have led to significant rises in mining operation costs.

¹inflation.eu, "Historic inflation South Africa - cpi inflation." [Online] <http://www.inflation.eu/inflation-rates/south-africa/historic-inflation/cpi-inflation-south-africa.aspx>, [Accessed 25 March 2017].

Figure 1.1: Electricity price increases between 2007 and 2017 [2] compared to the inflation rate in South Africa.¹

1.2.2 Process of a deep level mine

South Africa's mines are some of the deepest in the world. Some mine shafts are reaching depths deeper than 4000m below the surface [5]. The process of extracting ore at these depths is dependent on the essential services, mainly cooling and ventilation, pumping, compressed air and hoisting, as shown in figure 1.2.

Cooling and ventilation systems are required to maintain safe working temperatures underground. Pumping is critical to remove service and fissure water, preventing flooding. Compressed air is needed to safely power underground drills and machines. Finally, hoisting systems are used to bring the ore to the surface and to transport mine workers in the mine.

1.2.3 Mining Services

Energy usage

The mining industry uses extensive amounts of energy. In South Africa, the industry utilizes approximately 15% of the national electricity supplier's yearly output, of which, gold and platinum mines use 80%. [6]

Figure 1.3 shows the division of energy within the mining industry. The chart shows that compressed air systems utilise the most energy within a mining industry. It is reasoned that

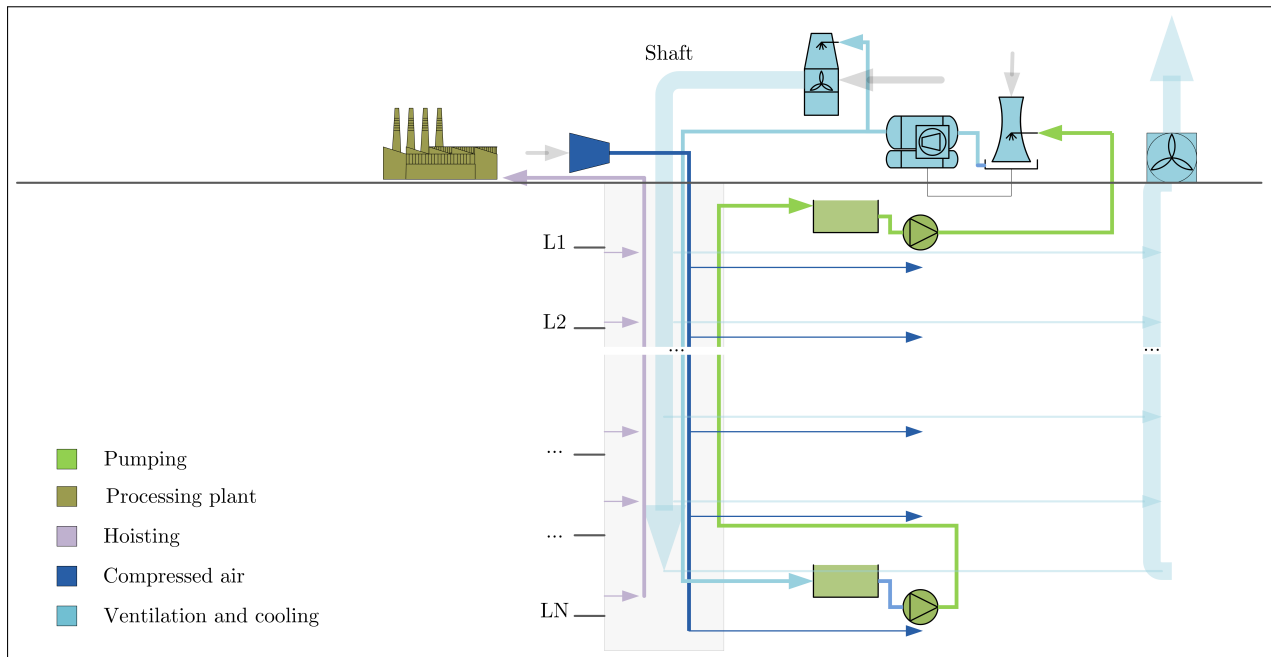

Figure 1.2: A layout showing the mining processes.

energy can be most effectively reduced through the implementation of energy interventions on compressed air systems.

Figure 1.3: The energy consumption for each mining system [7].

1.3 Compressed air systems in mining

1.3.1 Compressed air in operation

Largely due to their reliability, versatility and ease of use, the South African mining industry has installed extensive compressed air networks. These systems can have compressors with capacities of up to 15 Watt [8]. However, the supply of compressed air is a highly energy

demanding and costly process [9]. The energy used for compressed air production contributes to between 9% and 20% of the total mining energy consumption [6],[10].

Large compressed air systems are likely inefficient. Internationally, the expected energy savings potential of a large compressed air network is 15% [11]. Marais [12] showed that energy savings of up to 30% and 40% can be attained through various interventions.

Pneumatic rock drills

Drilling is mainly performed in the production areas or stopes of a mine. Drill machines are used to drill holes into the rock face. Once the holes have been drilled, explosives are then installed to break up the rock [13].

Compressed air is used to power pneumatic rock drills within a mine. Pneumatic rock drills run at an efficiency of 2%. This is low when compared to alternative rock drills such as electric, oil electro-hydraulic and hydro-powered drills that run at an efficiency of between 20-31% [14],[15].

Refuge bays

Refuge bays are installed in mines to provide safety to miners during emergencies. Most mines will utilise compressed air to deliver safe, cool air to the refuge bay. The provision of 1.42 l/s of air per person at a pressure between 200 and 300 kilopascals is required to provide oxygen and prevent any poisonousness gas entering the refuge [16].

Airflow in the refuge bays can be controlled with a manual valve within the chamber. Any many cases, this valve is often misused by mine workers who open the valves fully in order to cool the bay through the decompression of the air. *** need source ***

Processing plants

Large processing plants are constructed near gold and mines to extract metal from the ore. These plants utilise compressed air for various systems, processes and instrumentation. Processing plants are often connected to the same compressed air network as the mine [8]. The plants use relatively low amounts of air compared to mines, however they can have

pressure requirements that can complicate compressed air network optimisations .

Other compressed air usages

Due to the availability underground, compressed air is utilised for a number of other applications. These usages include, pneumatic loaders or rock shovels, pneumatic cylinders, dam sediment agitation, cooling and ventilation and many other applications. This vast variety of applications also leads to misuse of compressed air this leads to inefficient operation.

Compressed air control

On many large compressed air networks, the intake guide vane position on a compressor is manipulated in order to obtain the air flow and pressure requirements. Typically, guide vanes are opened and closed to increase and decrease the compressors discharge pressure. When more pressure is required than can be obtained with the guide vanes fully opened, another compressor is needed to operate.

As shown in the figure 1.4, showing guide vane positions vs power for a typical mining compressor, the guide vanes are controlled between 40% and 100% of their fully open position. Reducing and increasing the guide vane position will effect the power output of the compressor. The relationship between power and guide vane position of a compressor can be approximated as a linear function. A guide vane position of 40% will relate to an output power of about 60% of maximum power.

Figure 1.4: The relation between guide vane position and compressor output power.

Operation schedule

On a typical mine, various operations will take place at different times of the day. Depending on the activity taking place, many mines will control the pressure to meet the requirements [17],[8]. Figure 1.5 shows the schedule and pressure requirement on a typical deep level mine.

As shown in the figure, the pressure requirement changes depending on the activity taking place. The drilling shift typically has the highest pressure requirement whilst blasting shift requires the lowest. Schedules and operation philosophies can differ between mines. Different operational schedules require alternative pressure requirement profiles.

Figure 1.5: The typical operation schedule of a deep level mine [17].

1.3.2 Characteristic inefficiencies of compressed air systems

Compressed air distribution networks in the mining industry consist of multiple compressors and working areas up to eight kilometres away from the source [8]. Due to their size and complexity, these systems are prone to large energy losses.

Compressed air leakage accounts for as much as 35% of the energy losses of a compressed air network [18]. Other systemic losses include, faulty valves, pipe diameter fluctuations, obstructed air compressor intake filters and inefficient compressors.

1.3.3 Instrumentation and measurements

For large industrial systems, thorough instrumentation is necessary in order to monitor performance and condition throughout the system. In a mining compressed air network, instrumentation is installed on the compressor to monitor flows, pressures, temperatures and guide vane position. Electrical instrumentation is also installed for sensing currents, power factors, voltages and power. On control valves, input/output pressures, flows and valve position are usually measured with instrumentation.

Programmable logic controllers (PLCs). A Supervisory control and data acquisition (SCADA) system is used to observe and monitor all of the instrumentation.

When instrumentation is not installed. Manual measurements are performed.

Not finished

1.3.4 Inefficiency identification methods

Leakage and inefficiency detection strategies is not often pursued in the South African mining industry [15]. Many mines do however perform leak inspections either internally or by an outside company. In these inspections, an ultrasonic detector is used to locate the leak. Alternatively, some mines employ the “walk and listen” method to identify leaks from the audible sound that it produces [15]. Once the inspection is completed, the findings, including the locations and estimated costs of all identified leaks, are reported. Need to add a citation or two

1.3.5 Compressed air savings strategies

The main strategies for reducing energy on compressed air systems are summarised as follows [19]:

- Reducing leaks.
- Reducing demand.
- Reducing unauthorised usage.
- Increasing supply efficiency.
- Optimising supply.

Still need to discuss more detailed

1.4 Use of simulation in industry

1.4.1 Background in industrial simulation

Continuous improvements in computing hardware has led to major advancement in software technology. Consequently the use of computational simulation has become an increasingly valuable tool for many industries.[20]

In *Handbook of simulation: principles, methodology, advances, applications, and practice*, the advantages of the use of simulation in industry are discussed as follows [21]:

- The ability to test new policies, operating procedures and methods without causing a disruption to the actual system.
- The means to identify problems in complex systems by gathering insight in the interactions within the system.
- The facility to compress or expand time to investigate phenomena thoroughly.
- The capability to determine the limits and constraints within a system.
- The potential to build consensus with regard to proposed designs or modifications.

1.4.2 Simulation usage in mining

Simulation has been used to test and identify energy and operational improvements in mining systems. However, existing tools required too much data to model the systems accurately, [CITATION NEEDED] Resulting in simplified simulation models. New tools such the STB software, have made it possible to develop highly accurate, detailed simulations for mining systems. This will allow more complex intervention to be tested with more accuracy.

1.5 Problem statement and objectives

1.5.1 Problem statement

Rising costs and falling ore grades are driving in the mining industry to reduce operational inefficiencies. Large energy savings can be made in Compressed air systems in the mining industry. However manual testing of interventions can be cumbersome.

Computer modeling and simulation of compressed air systems can be used to quantify and priorities operational interventions that improve efficiency. These interventions can be evaluated with minimal risk. However simulations have not been utilized to their full potential in the mining industry. With new tools that allow for more detailed simulation models of mining systems could allow for of identification of more effective energy savings measures for mines.

1.5.2 Research objectives

The main objective of this dissertation is achieve energy savings and identify operational improvements in mining compressed air systems. A simulation process to will be developed to achieve this goal.

1.6 Dissertation overview

Describe (in approximately one sentence each) the contents of each of the dissertation chapters. No results here.

CHAPTER 2

Overview of simulation and compressed air applications

2.1 Introduction

2.2 Methods to identify operational improvements

2.2.1 Preamble

2.2.2 Identifying areas for improvement

(Kriel Masters) -Investigation

-Measurements

-Simulated impact of the proposed intervention

2.2.3 Measurements

2.2.4 Leakage detection

(Van Tonder masters) - Inspections

- Audible sounds (by ear)

- Ultrasonic

2.2.5 Estimation techniques

- Snyman estimated improvements using historical data.[19]

- Marais estimation through simplified estimation, simulation [8, 12].

2.2.6 Summary

2.3 Review of compressed air energy interventions in industry

2.3.1 Preamble

(Kriel Masters) - Supply and demand strategies (improving compressor efficiency vs reducing/improving demand)

Marais et al investigated increased energy savings through the use of Compressed Air Leakage Documentation System (CALDS) [22].

2.3.2 Strategies to improve compressed air supply

- Control Strategies
- Relocating compressor. reconfiguring networks - Bredenkamp
- Compressor schedules
- Variable speed drives
- Compressor selection
- Marais showed compressed air saving potential through an expert control system.[23]

2.3.3 Strategies to reduce/optimize compressed air consumption

- Reducing leaks
- Control Valves - Pascoe
- Marais PhD
- Snyman - investigated various Compressed air demand reduction and efficiency optimisations [19].

Pneumatic rock drills efficiency

Reduced pressure to the drill will cause it to run even less efficiently. A study by Bester *et*

al. showed that between 2002 and 2013 compressed air and energy consumption per tonne of ore produced had steadily increased as shown in figure 2.1. The increase in consumption per Tonne was a result of a reduction in air pressure at the mining stopes. Measurements indicated that the pressure was as low as 300 kilopascals. This reduced the efficiency of the rock drills. Before 2002 pressure was maintained above 500 kilopascals at the stopes. .[24]

2.4.6 Summary

2.5 Conclusion

CHAPTER 3

Developing a simulation methodology

‘*Quote.*’ - Somebody

3.1 Introduction

This chapter details the implementation methodology of simulations to optimize mining compressed air systems. The methodology discussed in this chapter will utilize insights from previous studies. Improving on shortcomings discussed in section 2.4.5.

Implementation of a simulation is split into three steps. Firstly, an investigation on the specific air network to is performed. The data acquired from this investigation is then utilized to develop and verify a simulation model. Finally scenarios are implemented using the simulations and the results are quantified and ranked. A simulation report is then produced and passed to the mine.

3.2 System investigation method

3.2.1 Preamble

Developing a detailed simulation model of a compressed air network requires thorough comprehension of the inner workings of the system. This section will discuss the investigations needed to obtain the required understanding.

3.2.2 Data acquisition and verification

- Layouts, data from SCADA Instrumentation, etc.
- Verification of accurate data - Gous article

3.2.3 Solutions to unavailable data

Parameters that are required to develop the simulation model, such as flows, pressures, may not be actively logged by mine systems. To obtain this data it is necessary to investigate alternative sources. At points where instrumentation is absent, estimations can be made from assumptions made using instrumentation on the network or spot inspections.

Air network specifications such as piping sizes, technical layouts, major leak locations or specifications is often outdated or not recorded. Critical data should be obtained through

audits and inspections of the system. If manual inspection is not possible, estimations should be made using the available data or approximation techniques discussed in literature.

3.2.4 Mining schedule

A crucial aspect to developing an accurate model of a mining compressed air system is understanding the the operational philosophy of the mine. The schedule for operations such as drilling, blasting or cleaning can have a major impact on compressed air requirements at different times of the day. By utilizing the operational schedule, simulation scenarios can be optimized for the air requirements throughout the day.

3.2.5 Summary

3.3 Model development and verification

3.3.1 Preamble

Compressed air networks are comprised of components such as compressors, valves, pipes, etc. This section discusses the development and calibration and verification of component models that make up a compressed air simulation is.

3.3.2 Compressed air component models

Air pipes

Pressure losses occur over compressed air networks due to friction in the pipe, these losses should be taken into account in the simulation for large piping sections. A pipe model is used to account for these losses which are defined by the *Darcy-Weisbach equation*¹:

$$\Delta P = \frac{fL\rho V^2}{2D}$$

¹ B. Glenn, ‘The Darcy–Weisbach Equation,’[Online] <https://bae.okstate.edu/faculty-sites/Darcy/DarcyWeisbach/Darcy-WeisbachEq.htm>, [Accessed 20-05-2017]

Where the pressure difference ΔP is a function of:

f	Friction coefficient
L	Pipe length (m)
D	Pipe diameter (m)
ρ	Air density (kg/m^3)
V	Average velocity (m/s)

The pipe component can be used as a valve by controlling the open fraction between 0 and

1. Modelling the valve flow characteristics is discussed in 3.3.2 *Controllers*.

Ambient conditions

Ambient air condition underground and on surface can effect the performance of the network [Citation needed]. Pressure and temperature increases with depth as a result of auto compression and rock face temperature [Citation needed]. Therefore it is important to take into account conditions for the boundary conditions at each mining level or area where compressed air is used.

Compressors

Three compressor models were investigated, each with varying complexity. The models are: air compressor, dynamic compressor and positive displacement compressor. The air compressor is a general, simplified model. It requires minimal user inputs by making several assumptions. This is useful when parameters for a compressor are not available. Or when doing a quick preliminary simulation. However it is not ideal for detailed simulations which require more precision.

The dynamic compressor components are is more complex, taking into account factors such as heat generated by polytropic coefficient and inefficiencies within the process. Hence the model can be used more accurately and for more complex simulations then the general compressor model. However, it should be noted that the dynamic compressor is simplified by several assumptions, for example, a constant efficiency at varying loads.

For most scenarios, the dynamic compressor model is most suitable. This component is

modelled by fitting a quadratic curve through three points of operation to obtain an equation for corrected mass flow as a function of the pressure ratio. This characteristic curve of compressor as shown in figure 3.1 can be accurately estimated even when only one data point is available by making approximations for the zero flow and pressure points on the curve. Once the flow characteristics of the compressors are set, the efficiency and polytropic coefficient parameters are calibrated such that the output power and air temperature match the actual or estimated outputs of the compressor.

Figure 3.1: Estimating the characteristic curve of a compressor by fitting a quadratic function to points of operation.

Once the models are accurately calibrated, the compressor component is integrated to the air network in the arrangement shown in figure 3.2. The Compressor is connected to the inlet air source via an inlet pipe and air node and to the rest of the network via an air node and outlet pipe. This is to allow the inlet and outlet parameters and conditions to be monitored and controlled.

Figure 3.2: Integrating the compressor component into the simulation.

Demand/leak

A flow demand represents any air flow leaving the network. This includes equipment that uses air such as drills and agitators etc. as well as inefficiencies like leaks and open pipes.

Generally the air flow is dependant on pressure and the specific resistance to flow of the outlet.

The specific resistance of the flow demand can be obtained using the inlet pressure, outlet pressure and flow. If the flow is not known, a reasonably accurate estimation can be made by calculating the expected flow from the size of the outlet.

Controllers

Simulation components need to be dynamically controlled as in the actual air network. Control is typically implemented on compressors and valves throughout the network to follow certain set-points and schedules. It is important to not only include the controllers in the simulation, but to replicate the non-linearities, limitations and responsiveness related to their use. This ensures the model reacts in the same way the actual network would, improving accuracy.

On a typical mine, compressors power is controlled to ensure that the discharge pressure matches a specified set-point. This control is achieved through either Variable Speed Drives (VSDs) (or Variable Frequency Drives (VFDs)) and guide-vain control. VFDs gives a wide range of power control and can be estimated using a Proportional-Integral (PI) controller as in figure 3.3 where discharge pressure is used as feedback for the controller. A guide

Figure 3.3: Control components in STB.

vain controller is modelled using a PI controller, as with the VSD controller. However the limitations of guide vain control, as shown in figure 1.4, must be implemented to the controller. This is done by adding a minimum output that would match the minimum factor of power reduction the guide vain achieved by closing the guide vain. Figure 1.4 shows that the typical minimum guide vain control position of 40% will map to a output power of approx. 60% of the maximum output power of the compressor.

Mines utilise control valves underground sections to control the pressure at individual mining stations independently [25]. Controlling of valve components is performed similarly as control of the compressor components. As shown in figure 3.3 the outlet pressure is used as feedback for a pi controller. The controller output is mapped to the valve fraction of a pipe component.

Figure 3.4: An example of a compressed air control valve[26].

Compressed air after-cooling

The air compression process generates significant heat. Compressed air at high temperatures contains a large amount of water vapour. To prevent condensation later in the air network, improve the system capacity and protect equipment from excessive heat, after-coolers are installed to the outlet of the compressor [27].

After-cooling reduces the compressed air temperature to within a margin of ambient. This cooling could have a large effect on the performance of the network. Hence including after-cooling to the simulation model should improve accuracy.

To replicate this effect, a heat transfer node can be added to the outlet of the compressor component. STB utilizes the following heat transfer parameters of the air node to solve for outlet temperature:

$Area$	The heat transfer area (m^2)
UA	Heat transfer coefficient ($kW/^\circ C$)
T_{amb}	Ambient air temperature ($^\circ C$)
